Observations of nearshore infragravity waves: Seaward and shoreward propagating components

A. Sheremet, R. T. Guza, S. Elgar, and T. H. C. Herbers

Received 14 May 2001; revised 5 December 2001; accepted 20 December 2001; published XX Month 2002.

[1] The variation of seaward and shoreward infragravity energy fluxes across the shoaling and surf zones of a gently sloping sandy beach is estimated from field observations and related to forcing by groups of sea and swell, dissipation, and shoreline reflection. Data from collocated pressure and velocity sensors deployed between 1 and 6 m water depth are combined, using the assumption of cross-shore propagation, to decompose the infragravity wave field into shoreward and seaward propagating components. Seaward of the surf zone, shoreward propagating infragravity waves are amplified by nonlinear interactions with groups of sea and swell, and the shoreward infragravity energy flux increases in the onshore direction. In the surf zone, nonlinear phase coupling between infragravity waves and groups of sea and swell decreases, as does the shoreward infragravity energy flux, consistent with the cessation of nonlinear forcing and the increased importance of infragravity wave dissipation. Seaward propagating infragravity waves are not phase coupled to incident wave groups, and their energy levels suggest strong infragravity wave reflection near the shoreline. The cross-shore variation of the seaward energy flux is weaker than that of the shoreward flux, resulting in cross-shore variation of the squared infragravity reflection coefficient (ratio of seaward to shoreward energy flux) between about 0.4 and 1.5.

INDEX TERMS: Oceanography: Physical: Nearshore processes; 4560 Oceanography: Physical: Surface waves and tides (1255); 4594 Oceanography: Physical: Instruments and techniques; KEYWORDS: infragravity waves, energy flux, surf zone, nonlinear phase coupling, shoreline reflection, cross-shore evolution

1. Introduction

[2] Over a distance of just a few wavelengths on a moderately sloped beach, shoreward propagating sea and swell (periods of roughly 4–20 s) steepen, pitch forward, break, and form dissipative bores. This evolution is accompanied by the generation of gravity waves with periods of a few minutes (infragravity waves). Here field observations are used to estimate the variation of seaward and shoreward infragravity energy fluxes across the shoaling and surf zones.

[1] Previous field observations have shown that standing waves can be a dominant component of the nearshore infragravity wave field [e.g., Suhayda, 1974; Hunkley, 1976; Hunkley et al., 1981; Oltman-Shay and Howd, 1993]. Standing infragravity waves are consistent with relatively weak forcing and damping and strong shoreline reflection. However, there also is evidence that a substantial progressive infragravity component can result from nonlinear forcing of shoreward propagating infragravity waves by groups of sea and swell [e.g., Munk, 1949; Longuet-Higgins and Stewart, 1962; Meadows et al., 1982; Elgar and Guza, 1985; List, 1992; Herbers et al., 1994]. Nonlinearly forced shoreward propagating and free seaward propagating (resulting from shoreline reflection) infragravity waves are expected to have different cross-shore amplitude variations, leading to partially standing waves. Observations in 13 m water depth, 2 km offshore Duck, North Carolina (the site of the observations presented here), show that the net (integrated over the infragravity frequency band) energy flux can be directed either seaward or shoreward and that the ratio of seaward to shoreward fluxes (hereinafter the bulk infragravity reflection coefficient $R^2$) deviates substantially from 1, with values usually between 0.5 and 4.0 [Elgar et al., 1994; Herbers et al., 1995b]. Reflection coefficients $R^2 < 1$ imply an energy sink (source) between the shoreline and 13 m depth observation sites. Three $R^2$ regimes were identified. With low sea-swell energy the infragravity wave field was dominated by arrivals from remote sources that were either partially dissipated or scattered into trapped waves shoreward of 13 m depth, and $R^2 < 1$. With moderate sea-swell energy, infragravity energy generated onshore of 13 m depth and radiated seaward exceeded dissipation and trapping losses, and $R^2 > 1$. With the most energetic sea and swell waves the 13 m depth observations were near the surf zone where dissipation might be important, and $R^2 < 1$. Nonlinear phase coupling of infragravity waves to groups of sea and swell seaward of the surf zone (depths between about 8 and 200 m) has been investigated with observations in the Atlantic and Pacific Oceans [Herbers et al., 1994, 1995b]. The observed levels of phase coupling, estimated with bispectral analysis, agreed well with the theory for second-order bound waves driven by quadratic, nonresonant, sea-swell interactions [Hasselmann, 1962], and both the bound wave energy levels and the ratio of bound to total (free plus bound) infragravity energy increased with increasing sea-swell energy and decreasing depth. Similar increases in nonlinear phase coupling were observed in pressure measurements seaward of the surf zone (in 3–6 m depth) [Ruessink, 1998]. However, the coupling decreased to approximately zero when the offshore sea-swell energy was so large that the observations were within the surf zone.
2. Field Experiment and Analysis

Observations were obtained from August to December 1997 during the Sandyduck experiment conducted on a sandy beach near Duck, North Carolina. A two-dimensional array of electromagnetic current meters, downward looking sonar altimeters, and pressure sensors was deployed in 1–6 m depth (described in section 2) to decompose the infragravity wave field into shoreward and seaward propagating components. Errors introduced by neglecting the directionality of the infragravity wave field are shown to be small in Appendix A. The spatial variation of infragravity energy fluxes is related to forcing by groups of sea and swell, dissipation, and shoreline reflection in section 3. The directionality of infragravity waves is discussed briefly in section 4, and a more detailed analysis is presented by A. Sheremet et al. (manuscript in preparation, 2002). Results are summarized in section 5.

[4] Here a more detailed analysis of the transformation of infragravity waves through the shoaling and surf zones is presented using extensive new observations. Collocated current meters and pressure sensors deployed in 1–6 m depth (described in section 2) are used to decompose the infragravity wave field into shoreward and seaward propagating components. Errors introduced by neglecting the directionality of the infragravity wave field are shown to be small in Appendix A. The spatial variation of infragravity energy fluxes is related to forcing by groups of sea and swell, dissipation, and shoreline reflection in section 3. The directionality of infragravity waves is discussed briefly in section 4, and a more detailed analysis is presented by A. Sheremet et al. (manuscript in preparation, 2002). Results are summarized in section 5.

Bulk infragravity energies, fluxes, and reflection coefficients were obtained from each collocated $p - u$ sensor pair. Estimates from the same alongshore array (Figure 1) were averaged. Errors in the bulk fluxes and $R^2$ owing to the assumption of normal incidence are estimated to be <20% (Appendix A). To eliminate observations with significant nongravity motions (e.g., shear waves), 3 hour runs with a mean alongshore velocity >50 cm s$^{-1}$ at any current meter were excluded. Frequency–alongshore wave number spectra (T. J. Noyes, personal communication, 2000) confirm that nongravity wave motions contribute generally <20% of the infragravity velocity variance in the 680 runs retained in this study. Linear finite depth theory was applied to pressure data in 8 m depth to estimate $E_{ui,8m}$, the sea-swell energy integrated over the frequency band 0.05–0.24 Hz. Significant wave heights in 8 m depth, $H_{1/3,8m} = 4^{\frac{\theta}{2}}$, in the retained 3 hour runs ranged from 0.2 to 2.7 m.

Quadratic difference-frequency interactions between sea-swell components with slightly different frequencies ($f$ and $f + \Delta f$) are always nonresonant in intermediate and deep (for the sea and swell waves) water depths and theoretically result in a bound infragravity wave of frequency $\Delta f$ that does not satisfy the linear dispersion relation. In this nonresonant case the doubly integrated, normalized bispectrum ($b_{ii}$, in equation (9) of Herbers et al. [1994] and $\mu$ here) is proportional to the fraction of the total infragravity wave energy contained in bound components. In contrast, when the water depth is shallow for the sea and swell, near-resonant quadratic difference-frequency interactions can result in gradual (over several wavelengths) alteration of the phase and energy of free infragravity waves. In this case the real and imaginary parts of the bispectrum are related to the rate of nonlinear phase change (wave number shift) and nonlinear energy exchange, respectively [Herbers and Burton, 1997; Herbers et al., 2002]. Therefore, in the shallow
depths considered here, $\mu$ (incorporating both real and imaginary parts of the bispectrum) is interpreted qualitatively as a nondimensional measure of the strength of near-resonant forcing of free infragravity waves by quadratic interactions with sea and swell.

Calculating $\mu$ from observed pressure or velocity time series mixes information about seaward and shoreward propagating infragravity waves. Following Elgar and Guza [1985], nonlinear coupling also was estimated from time series of pressure fluctuations containing only shoreward or only seaward propagating infragravity waves ($\mu^+$ and $\mu^-$, calculated using $\eta$ and $\eta^-$ (equation (1)), respectively). An error in accounting for the effect of time domain windowing in previously reported bispectral integrals [Herbers et al. 1994, 1995a; Raesink, 1998] is corrected below, resulting in $\mu$, $\mu^+$, and $\mu^-$ values that are a factor of 0.58 lower than uncorrected values.

3. Results

Similar to previous observations [e.g., Sabayda, 1974], at a fixed infragravity frequency the observed cross-shore variation of spectral levels of pressure (Figures 2a and 2b) and cross-shore velocity (Figures 2c and 2f) have minima and maxima close to the theoretical locations of standing wave nodes and antinodes. Note that the observed $u$ spectral maxima and $p$ spectral minima occur at the same location (e.g., $x = 185$ m), in contrast to a progressive wave field where the spatial variations of $u$ and $p$ spectral levels are similar and do not have a structure with nodes and antinodes. The observed phase differences between spatially separated $p$ time series (Figures 2c and 2d) and between collocated $p$ and $u$ time series (Figures 2g and 2h) also suggest substantial shoreline reflection. With a progressive wave field on a gently sloping bottom the phase difference between spatially separated time series increases approximately linearly with increasing separation along the propagation direction, and the phase between collocated $p$ and $u$ is zero. At the representative infragravity frequency (0.014 Hz) shown in Figure 2, strong reflection is confirmed by the $R^2(f)$ estimates (based on collocated pressure and cross-shore velocity observations equations (2) and (3)) in the range $0.2$–$0.8$ (Figures 2i and 2j). As discussed by Sheremet et al. (manuscript in preparation, 2002), similar reflection coefficient estimates are obtained when spatially separated sensors are
included in the analysis. Individual frequency bands are not considered further here.

[12] In both wide (\(H_{\text{sig,8m}} = 2.0\) m) and narrow (\(H_{\text{sig,8m}} = 1.0\) m) surf zone cases, infragravity wave reflection is significant (Figures 3e and 3f), whereas sea-swell reflection is weak (Figures 3a and 3b). The bulk shoreward infragravity flux \(F^+\) increases shoreward in the region where \(\mu^+\) is large (roughly \(x \geq 385\) m in Figures 3c and 3g and \(x \geq 175\) m in Figures 3d and 3h). Within the surf zone, \(\mu^+\) decreases to negligible values, and the growth of \(F^+\) ceases (with the exception of one observation at \(x = 175\) m in Figure 3c). Seaward propagating infragravity waves are not coupled to groups of sea and swell (\(\mu^-\) is small everywhere; Figures 3g and 3h). The bulk reflection coefficient \(R^2\) (equation (4)) decreases from values as large as 1.5 far seaward of the surf zone (Figure 3f) to between about 0.5 and 1.0 within the surf zone (Figures 3c and 3f). At the location nearest the shoreline, \(R^2 \approx 1\). These trends are consistent with the hypotheses [e.g., Longuet-Higgins and Stewart, 1962] that \(F^+\) increases in the shoaling region owing to nonlinear forcing by sea-swell groups, that sea-swell breaking reduces the nonlinear forcing, and that shoreward propagating infragravity waves are reflected strongly at the shoreline.

[13] At the most offshore \(p-u\) location (\(x = 500\) m) the seaward \(F^-\) and shoreward \(F^+\) fluxes both increase with increasing \(E_{\text{ss,8m}}\) (Figures 4a and 4c). For all \(E_{\text{ss,8m}}\), \(F^-\) at \(x = 210\) m (5–6 m depth) and \(x = 210\) m (2–3 m depth) are approximately equal (their ratio is about 1.2; Figure 4b). In contrast, the ratio of \(F^+\) at \(x = 210\) m to \(F^-\) at \(x = 500\) m is as large as 3 with moderate \(E_{\text{ss,8m}}\) and is <1 with the largest \(E_{\text{ss,8m}}\) (Figure 4d).

[14] At the deepest (5–6 m depth) location the dependence of the bulk reflection coefficient \(R^2\) on \(E_{\text{ss,8m}}\) (Figure 5a) is similar to that observed in 13 m depth [Herbers et al., 1995b, Figure 5]. For moderate values of \(E_{\text{ss,8m}}\), \(R^2 > 1\), whereas for the largest and smallest \(E_{\text{ss,8m}}\), \(R^2 < 1\). However, the maximum \(R^2\) values here are about 1.5, lower than those observed (as high as 4.0) in 13 m depth.

\[ \text{Figure 3.} \] (a) and (b) Bulk seaward and shoreward sea-swell energy fluxes; (c) and (d) bulk seaward and shoreward infragravity energy fluxes; (e) and (f) bulk infragravity reflection coefficient \(R^2\); and (g) and (h) measures of nonlinear phase coupling \(\mu^+\) versus cross-shore location \(x\) (left) 7 November 1997, 0700–1000 LT, \(H_{\text{sig,8m}} = 2.0\) m and (right) 10 September 1997, 0100–0400 LT, \(H_{\text{sig,8m}} = 1.0\) m. The \(\mu^+\) biphases, not shown, are close to 180°, as observed by Ruessink [1998]. Circles and crosses correspond to shoreward and seaward infragravity wave propagation, respectively. Note the different vertical scales for fluxes in the left and right panels.
Closer to shore \((x = 210 \text{ m})\), \(R^2 < 1\) for all \(E_{ss,8m}\) (Figure 5b). Although values are scattered, at both locations the mean \(R^2\) decreases with large and increasing \(E_{ss,8m}\). At both locations the nonlinear coupling \(\mu^+\) increases as \(E_{ss,8m}\) increases from the lowest levels, reaches a maximum at intermediate \(E_{ss,8m}\) values, and then decreases with further increases in \(E_{ss,8m}\) (Figures 5c and 5d).

[15] On the basis of similar variations of observed \(\mu\) with \(E_{ss}\), Ruessink [1998] suggested that the intense wave breaking in the surf zone reduces the forcing of infragravity waves. The dependence of the normalized infragravity fluxes and nonlinear coupling on the reduction of sea-swell energy flux in the surf zone \((F_{ss}'\text{ normalized})\) by the flux in 8 m depth, \(F_{ss}'\text{,8m}\), is shown in Figure 6. Values of the normalized sea-swell flux \(F_{ss}'\text{,8m}/F_{ss,8m}\) close to 1 correspond to observations seaward of the surf zone, and lower values are progressively farther within the surf zone. The normalized shoreward infragravity flux \(F^+\text{,}500/F_{ss,8m}\) increases as \(F_{ss}'\text{,8m}/F_{ss,8m}\) decreases from 1, reaches a maximum for \(F_{ss}'\text{,}500/F_{ss,8m}\approx 0.5\), and then decreases in the inner surf zone (Figure 6a). This decrease suggests significant damping of infragravity waves in the surf zone. Similar to the nonlinear coupling of the total infragravity field \(\mu\) to groups of sea and swell [Ruessink, 1998], the coupling of shoreward propagating infragravity waves \(\mu^+\) is reduced greatly in the surf zone (Figure 6b), consistent with the cessation of nonlinear forcing.

[16] Although the dependence of infragravity wave properties on the normalized sea-swell flux \(F_{ss}'\text{,}8m\), demonstrates the important role of sea-swell breaking, all observations seaward of the surf zone are collapsed into \(F_{ss}'\text{,}8m/F_{ss,8m}\approx 1\). Consequently, the variation of infragravity fluxes observed in the shoaling region (i.e., \(x \geq 175 \text{ m}\) in Figure 3d) is obscured. To include this spatial variation, infragravity wave properties are shown (Figure 7) as functions of the normalized cross-shore position \(x/x_{50}\), where \(x_{50}\) is the location where \(F_{ss}'\text{,}8m\) is 50% of \(F_{ss,8m}\) and the shoreward infragravity flux is maximum (Figure 7a). \(F^+\text{,}500/F_{ss,8m}\) increases in the shoaling region, attains a maximum at about \(x/x_{50} = 1.0\), and then decreases (Figure 7a). The coupling \(\mu^+\) is nearly constant through the shoaling region, then starting at the outer edge of the surf zone \((x/x_{50} \approx 2)\) decreases sharply to negligible values in the inner surf zone \((x/x_{50} < 1)\) (Figure 7b). Seaward propagating infragravity waves are not phase coupled to sea-swell groups (\(\mu^+\) always is small; Figure 6b), and the energy flux of the unforced shoreward propagating waves \(F^-\) is less spatially variable than the flux \(F^+\) of the nonlinearly forced shoreward propagating waves (Figure 7a). Dissipation and refractive trapping, discussed by A. Sheremet et al. (manuscript in preparation, 2002), both contribute to the decrease in \(F^-\) with increasing offshore distance from the shoreline.

[17] The dependence of \(R^2\) estimates on \(x/x_{50}\) is shown in Figure 8, including additional estimates farther from shore based on array measurements in 8 m depth. Although the analysis methods are different, \(R^2\) estimates based on nearshore collocated \(p, u\) observations and offshore array measurements (analyzed without the assumption of normal incidence [Herbers et al., 1995b]) overlap smoothly at intermediate \(x/x_{50}\) values (Figure 8). Far offshore of the surf zone (largest \(x/x_{50}\), \(F^- > F^+\) and the bulk reflection coefficient \(R^2\) approaches 1.6 (Figure 8). During shoaling, \(F^+\) increases, but \(F^-\) remains relatively constant (Figure 7a), and \(R^2\) decreases with further increases in \(E_{ss,8m}\).
decreases to a minimum of about 0.5 near $x/x_{50} = 1$. In the inner surf zone ($x/x_{50} < 1$) where $F^-$ decreases toward shore (presumably owing to dissipation), $R^2$ increases again to a maximum value of about 0.8 at the shoreline where the infragravity waves are strongly reflected.

Numerical and laboratory studies suggest that infragravity energy also may be generated by fluctuations of surf zone width and setup at infragravity periods [Symonds et al., 1982; Lippmann et al., 1997]. Although such generation is not precluded by the results presented here, much of the observed growth in $F^-$ occurs well seaward of the surf zone and thus offshore of the region where generation by a time-varying breakpoint theoretically occurs.

4. Directionality of Infragravity Waves

The method used here to estimate the shoreward and seaward propagating infragravity wave components is based on the assumption of near shore normal propagation. Although the energy flux and $R^2$ estimates are not degraded significantly by the infragravity wave obliquity in these data (Appendix A), obliquity could be associated with refractively trapped edge waves. As in previous studies in similar water depths [e.g., Huntley et al., 1981; Oltman-Shay and Howd, 1993], frequency and frequency–wave number spectra show deviations from normal incidence. In cases with large mean incident angles the spectral levels of $v$ often are within a factor of 2–3 of the cross-shore velocity $u$ levels (Figure 9a). At infragravity frequencies, frequency–alongshore wave number spectra of $p$, $u$, and $v$ ($p$ is shown in Figure 9b) have variance maxima at wave numbers within the edge wave range. On the basis of frequency–alongshore wave number spectra and the qualitative standing wave character of the cross-shore variation of infragravity phases and variance (Figures 2b, 2d, 2f, and 2h), observations similar to these have been interpreted as consistent with edge waves, the normal mode solutions of gravity waves undergoing multiple reflections between the shoreline and an offshore turning point. However, the cross-shore analysis for this run shows a substantial progressive shoreward energy flux (Figure 3f) that suggests that a significant fraction of the energy is lost before waves reach the shoreline. This motivates the consideration of strongly damped edge waves by A. Sheremet et al. (manuscript in preparation, 2002).

5. Conclusions

Observations of pressure and velocity collected in water depths between 1 and 6 m are used to estimate the seaward and shoreward energy fluxes of infragravity waves. Although there is
and seaward propagating \((m)\) flux in 8 m depth shoreward sea-swell energy flux \((F_{ss})\) by Appendix A: Error Estimates for reflected strongly. increases to about 0.8 at the shoreline where infragravity waves are zone, reaches a minimum of about 0.4 in the outer surf zone, and infragravity reflection coefficient exceeds 1 far seaward of the surf zone, consistent with both dissipation and important. The seaward infragravity flux decreases with increasing distance from the shoreline, amplified in the shoaling zone by nonlinear interactions with shoreward propagating infragravity waves and sea-swell groups of the total \((\mu, \text{crosses})\), shoreward propagating \((\mu, \text{circles})\), and seaward propagating \((\mu, \text{crosses})\) infragravity wave fields versus the shoreward sea-swell energy flux \(F_{ss}^+\) normalized by the sea-swell flux in 8 m depth \(F_{ss,8m}^+\). The vertical bars indicate ±1 standard deviation about the mean. When offshore sea and swell energy are low, the dominant infragravity waves often are arrivals from remote sources [Herbers et al., 1995b]. To focus on locally generated infragravity waves, 385 3 hour runs with \(E_{ss,8m} > 400 \text{ cm}^2\) are used.

Considerable scatter, on average the shoreward infragravity flux increases during shoaling when the nonlinear coupling between shoreward propagating infragravity waves and sea-swell groups is strongest. Within the surf zone, coupling is reduced strongly, and the shoreward flux decreases, consistent with the cessation of forcing and increased dissipation. Reflection is strong at the shoreline. The coupling of seaward propagating infragravity waves to sea-swell groups always is weak. The results support the existing hypothesis that shoreward propagating infragravity waves are amplified in the shoaling zone by nonlinear interactions with sea-swell groups and strongly reflected near the shoreline. Damping of infragravity waves in the surf zone also appears to be important. The seaward infragravity flux decreases with increasing distance from the shoreline, consistent with both dissipation and refractive trapping, but is less spatially variable than the shoreward flux. As a result of these spatially varying energy fluxes, the bulk infragravity reflection coefficient exceeds 1 far seaward of the surf zone, reaches a minimum of about 0.4 in the outer surf zone, and increases to about 0.8 at the shoreline where infragravity waves are reflected strongly.

Appendix A: Error Estimates for \(R^2\) and \(F^+\)

[21] Errors in infragravity energy fluxes and reflection coefficients estimated using collocated observations of pressure \(p\) and cross-shore velocity \(u\) and the assumption of normal incidence (equations (2) and (3)) are examined using linear WKB theory for shallow-water waves. The cross-shore and the alongshore coordinates are \(x\) and \(y\), and the \(x\) origin is at the shoreline. Assuming that the depth varies only in the cross-shore direction, \(h = h(x)\), the pressure time series can be expressed as a superposition of Fourier modes with different frequencies \(f\) and alongshore wave numbers \(k_x\):

\[
p(t, x, y) = \int_{-\infty}^{\infty} df \int_{-\infty}^{\infty} P(f, x, k_x) e^{i(\omega t + q_x x + q_y y)} d\omega d\phi,
\]

or, equivalently, incidence angles \(\theta(f, x)\):

\[
p(t, x, y) = \int_{-\infty}^{\infty} df \int_{-\pi}^{\pi} P(f, x, 0) e^{i(k \sin \theta x)} d\theta,
\]

where \(P\) is the cross-shore structure of a Fourier mode and \(k = k(f, x)\) is the local wave number modulus. Normal incidence corresponds to

Figure 6. (a) Average values of bulk shoreward \(F^+\) (circles) and seaward \(F^-\) (crosses) infragravity energy fluxes normalized by \(F_{x,500}^+\), the seaward infragravity flux at \(x = 500\) m, and (b) bulk nonlinear phase coupling to sea-swell groups of the total \((\mu, \text{circles})\), shoreward propagating \((\mu, \text{circles})\), and seaward propagating \((\mu, \text{crosses})\) infragravity wave fields versus the shoreward sea-swell energy flux \(F_{ss}^+\) normalized by the sea-swell flux in 8 m depth \(F_{ss,8m}^+\). The vertical bars indicate ±1 standard deviation about the mean. To focus on locally generated infragravity waves, 385 3 hour runs with \(E_{ss,8m}^+ > 400 \text{ cm}^2\) are used.

Figure 8. Bulk infragravity reflection coefficient \(R^2\) versus normalized cross-shore location \(x/x_{50}\). Circles are estimates based on collocated \(p - u\) sensors (equation (1), depths <6 m), and squares are based on pressure array observations in 8 m depth. The 385 3 hour runs with \(E_{ss,8m}^+ > 400 \text{ cm}^2\) are used.
\( q = 0 \). A relation similar to equation (A1) can be written for \( U \), the cross-shore structure of the cross-shore velocity. \( P \) and \( U \) are assumed to have the form

\[
P(f, x, q) = \frac{1}{2} \left[ A^+ e^{i \phi + i \kappa x} + A^- e^{-i \phi + i \kappa x} \right],
\]

\[
U(f, x, q) = \frac{1}{2} \sqrt{\frac{g}{h}} \left[ A^+ e^{i \phi + i \kappa x} - A^- e^{-i \phi + i \kappa x} \right] \cos \theta,
\]

where \( A_\pm = A_s(f, x, 0) \) are the real amplitudes of shoreward (+) and seaward (−) propagating waves, \( \phi \) is an arbitrary phase, and \( \theta \) is the phase with respect to the shoreline

\[
\phi(f, x, 0) = \int_0^x k_0 ds = 2\pi f \int_0^x \frac{\cos \theta(f, s, 0)}{\sqrt{gh(s)}} ds,
\]

\( \theta = 0 \). The dashed curves in Figure 9b are edge wave dispersion curves for modes 0– and 25 (approximately the boundary between the leaky and trapped wave domains). The \( f - \kappa \) spectra at each \( f \) are normalized by the frequency spectra, and darker shades indicate higher spectral levels within each frequency band. Additional results for this run are shown in Figures 2(right) and 3(right).
Substituting equation (A4) into equations (2)–(3) yields the estimated energy fluxes at frequency $f$: \[
\frac{F}{C_6} = \sqrt{\frac{gh}{2}} \int_{-\pi/2}^{\pi/2} \left\{ \left( (A^+)^2 - (A^-)^2 \right) \cos 2\theta \right\} \cos \theta d\theta,
\]

where $\int_{-\pi/2}^{\pi/2} S(f, \theta) d\theta = 1$. Specular reflection and a true reflection coefficient $R_t$ that is independent of frequency and direction are assumed for simplicity. With $\mathcal{E}$ and $S$ assumed independent of frequency over the infragravity band the frequency-integrated fluxes are

\[
F^\pm = \sqrt{\frac{gh}{4}} \mathcal{E} \int_{-\pi/2}^{\pi/2} \left\{ \left( 1 + \cos^2 \theta \right) + \frac{2}{\Delta_x} \int df \int_{-\pi/2}^{\pi/2} S(\theta) R_t \sin(2\theta) \sin^2 \theta d\theta \right\},
\]

The amplitudes are related to the energy $\mathcal{E}$ and angular distribution $S$ of the shoreward propagating modes by

\[
\begin{align*}
(A^+)^2 &= 2\mathcal{E}^+(f, \theta) S(f, 0), \\
(A^-)^2 &= 2R_t^2 \mathcal{E}^-(f, \theta) S(f, 0), \\
A^+ A^- &= 2R_t \mathcal{E}^+(f, \theta) S(f, 0),
\end{align*}
\]

Figure A1. Contours of (a) $R_t^2$, (b) the magnitude of the maximum value attained by $|\beta|$ over a plane beach with a 0.02 slope, over the depth range 1–6 m, and (c) $F_0/F_t^+$ as functions of the mean direction $\theta_m$ and directional spread $\sigma$ (angular spread function $S(\theta)$ is defined in equation (A14)). Each dot represents the alongshore-averaged bulk infragravity mean direction and directional spread for a single 3 hour run at a given cross-shore location, computed with a method that utilizes both components of horizontal velocity [Herbers et al., 1999]. (d) The relative errors of $R_t^2$ and $F_0^+$ for $R_t^2 = 0.005$, $|\beta| = 0.0015$, and $F_0/F_t^+ = 1.1$ (e.g., the relative error for $R_t^2$ is defined as $(R_t^2/C_0 R_t^2)/R_t^2$) versus the true reflection coefficient $R_t^2$. 

\[
X_{ps}(f, x) = \frac{1}{2} \int_{-\pi/2}^{\pi/2} \left\{ \left( (A^+)^2 - (A^-)^2 + 2iA^+ A^- \cos 2\theta \right) \cos \theta d\theta \right\}
\]

Substituting equation (A4) into equations (2)–(3) yields the estimated energy fluxes at frequency $f$:

\[
\mathcal{F}^\pm = \sqrt{\frac{gh}{8}} \int_{-\pi/2}^{\pi/2} \left\{ \left( (A^+)^2 + (A^-)^2 \right) \left( 1 + \cos^2 \theta \right) \pm 2 \left( (A^+)^2 - (A^-)^2 \right) \cos \theta + 2A^+ A^- \left( 2\theta \right) \sin^2 \theta \right\} d\theta.
\]
where \( E^* \) is the total shoreward propagating energy in the infragravity band \( D_0 \) of width \( \Delta \omega_e \).

[23] To assess the errors in equation (A7), it is convenient to normalize by the true shoreward energy flux

\[
F_t^+ = \frac{\sqrt{\gamma h E^*}}{S(0)} \cos \theta d\theta, \quad \int_{-\pi/2}^{\pi/2} S(0) \cos \theta d\theta = \pi/2
\]

yielding

\[
\frac{F^+}{F_t^+} = \left( 1 + \beta R_i^+ R_t^+ R_0^+ \right) \frac{F_0^+}{F_t^+} (\approx 1 \ if \ F^+ \ is \ exact), \tag{A8}
\]

\[
\frac{F^-}{F_t^-} = \left( 1 + \beta R_i^- R_t^- R_0^- \right) \frac{F_0^-}{F_t^-} (\approx 1 \ if \ F^- \ is \ exact), \tag{A9}
\]

\[
\frac{R^2}{R_t^2} = \frac{1 + \beta R_i^+ R_t^+ R_0^+}{1 + \beta R_i^- R_t^- R_0^-} \approx 1 \ if \ R^2 \ is \ exact, \tag{A10}
\]

where \( R_0^- \) and \( F_0^- \) are the values of the estimated reflection coefficient and shoreward flux for \( R_t^- = 0 \) and

\[
R_0^+ = \frac{a - b}{a + b}, \quad F_0^+ = \frac{\sqrt{\gamma h}}{4} E^*(a + b), \quad \beta = \frac{c}{a + b}. \tag{A11}
\]

with

\[
a = \int_{-\pi/2}^{\pi/2} S(0)(1 + \cos^2 \theta) d\theta, \quad b = \int_{-\pi/2}^{\pi/2} 2S(0) \cos \theta d\theta
\]

\[
c = 2\Delta_f \int \frac{df}{\theta} \int_{-\pi/2}^{\pi/2} S(0) \sin(2\theta) \sin^2 \theta d\theta. \tag{A12}
\]

Assuming that the beach slope is constant, the integral (A3) becomes

\[
\psi(f, x, 0) = \frac{2\pi f x}{\sqrt{gh(x)}} \left[ \cos \theta + \frac{\theta}{\sin \theta} \right]. \tag{A13}
\]

[24] The errors in the estimates (A8)(A9)–(A10) can be calculated for a given \( R_t^0 \) if values of \( R_0^+ \), \( \beta \) and \( F_0^+ / F_t^+ \) are known. These depend on \( S(0) \) and are obtained by substituting in equation (A12) an analytic expression for \( S \) [Longuet-Higgins et al., 1963],

\[
S(\theta) = A \left[ \cos(0 - \theta_\text{m}) \right]^{2(\sin^2 - 1)}, \tag{A14}
\]

where \( A \) is a normalization constant, \( \theta_\text{m} \) is the mean propagation direction, and \( \sigma \) is the directional width. The dependence of \( R_0^+ \), \( \beta \) and \( F_0^+ / F_t^+ \) in equations (A8)–(A10) on \( \theta_\text{m} \) and \( \sigma \) is shown in Figures 10a–10c. The infragravity band was taken as 0.01–0.03 Hz (a wider bandwidth reduces the errors), and the beach slope was taken as 0.02 (approximately the average Duck slope over the span of the sensor array). Figure 10b shows the magnitude of the maximum of \( |S| \) over the depth range 1–6 m. For typical observed \( \theta_\text{m} \) and \( \sigma \), values of \( \beta \), \( R_0^+ \) and \( F_0^+ / F_t^+ \) are about 0.005, 0.0015, and 1.1, respectively. With these values the relative errors for \( R^2 \) and \( F^* \) do not exceed 20% for 0.05 < \( R_t^+ < 4 \) (Figure 10d). Note that because the fluxes \( F^* \) are overestimated by approximately the same amount, the flux ratio \( R^2 \) is more accurate than the fluxes.

[25] Acknowledgments. This research was supported by the Office of Naval Research, the National Ocean Partnership Program, and the Mellon Foundation. Staff from the Center for Coastal Studies, Scripps Institution of Oceanography, and from U.S. Army Corps of Engineers Field Research Facility, Duck, North Carolina, provided excellent logistical support. Britt Raubenheimer and Falk Feddersen contributed to the experiment. The 8 in array data were provided by the Field Research Facility. Woods Hole Oceanographic Institution contribution 10453.
